

Global non-linear effect of temperature on economic production

Marshall Burke, Stanford University

Solomon Hsiang, University of California, Berkeley

Edward Miguel, University of California, Berkeley

World Bank

September 2015

Motivation

- **Climate change** is one of the most important international development challenges of our time
 - Impacts are possible across a range of development areas, including agriculture, energy, health, migration, conflict, ...
- Projections of future climate impacts matter for (potentially expensive) policy decisions today, e.g., December 2015 Paris climate conference

Motivation

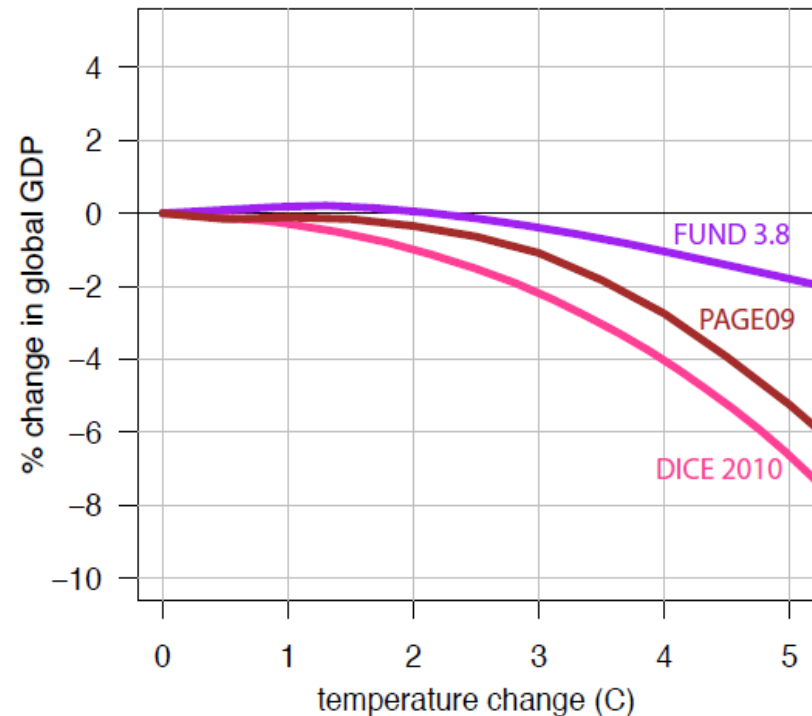

- **Key policy question:** what is the cost of emitting a ton of carbon today?

$$\text{Social cost of carbon} = \sum_{t=0}^{\infty} \underbrace{\delta^t \frac{\partial \text{Damage}}{\partial \text{Temp}_t}}_{\text{Economics}} \underbrace{\frac{\partial \text{Temp}_t}{\partial \text{CO2}_t} \frac{\partial \text{CO2}_t}{\partial \text{Emissions}_t}}_{\text{Climate science}}$$

- **Today's talk:** generate econometric estimates of the damage function with respect to economic growth

Damage functions in existing models

- Integrated assessment models (IAM's) are widely used in climate policy debates
- They assert that damages will be minimal up to 2-3 C, increasing beyond that
- Consider a -3% effect by 2100
- An economy growing 1% per year is 133% richer in 85 years
- With climate change of +4C, only 130% richer

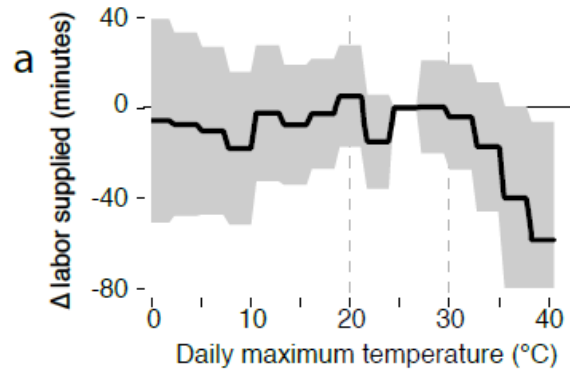

Damage functions in existing models

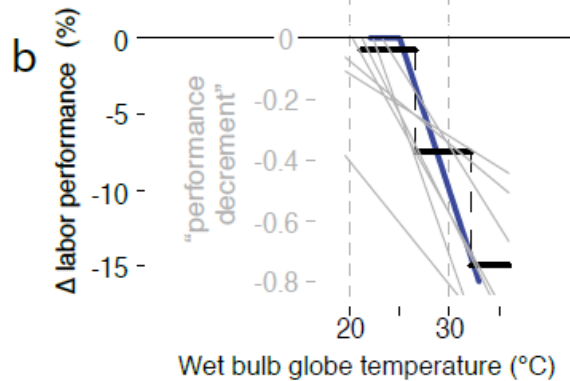

- So, no need to worry? Many critiques of these models:
 - 1) Pindyck (JEL, 2013): *“The damage functions used in most IAM’s are completely made up, with no theoretical or empirical foundation.”*
 - 2) Revesz, Arrow, Goulder, et al. (Nature 2014): *“The models should be revised more frequently to accommodate scientific developments.”*
- Limitations: developed in the 1990s; calibrated for moderate warming, not large changes; based mainly on out-of-date rich country estimates; ignore many plausible channels; do not allow for effects of climate on economic growth; ...

Recent micro-estimates of climate

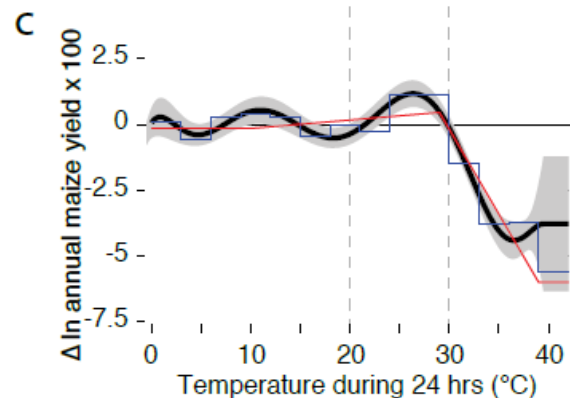

Labor supply
(Graff Zivin and
Neidell 2014)

Labor productivity
(Hsiang 2010)

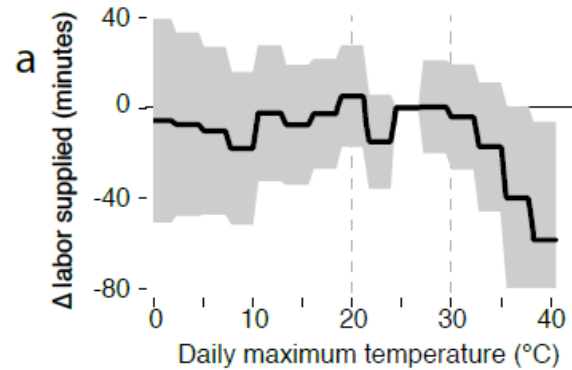

Crop yields
(Schlenker and
Roberts 2009)

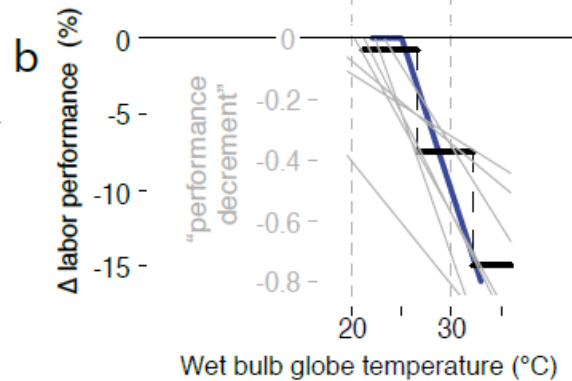

Linking micro-estimates to macro

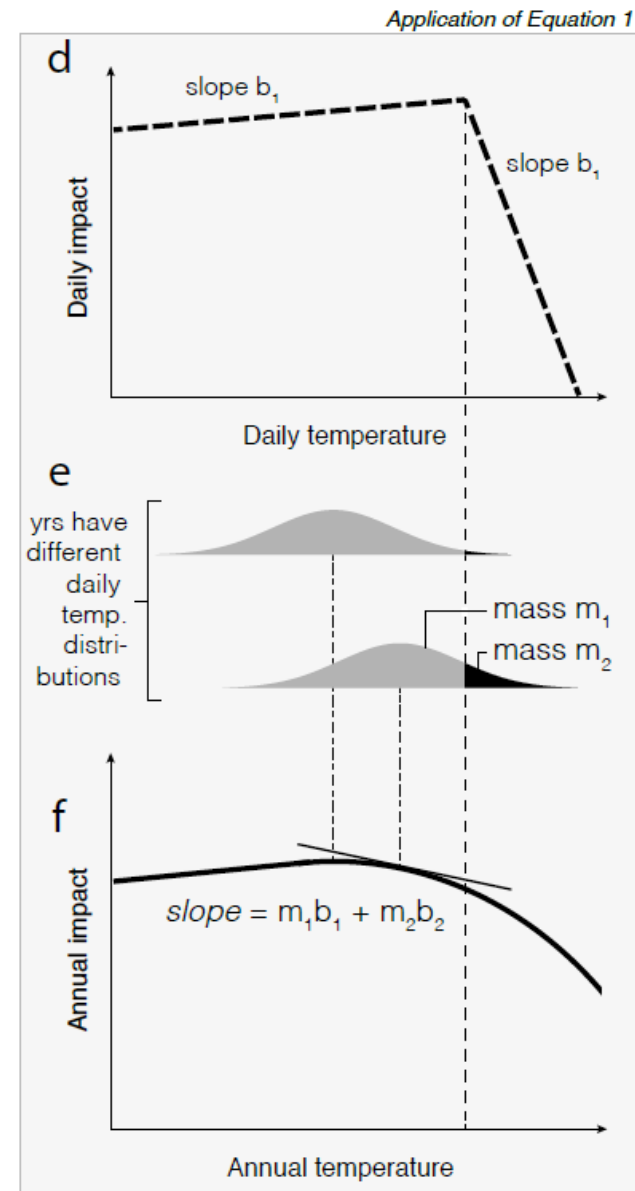

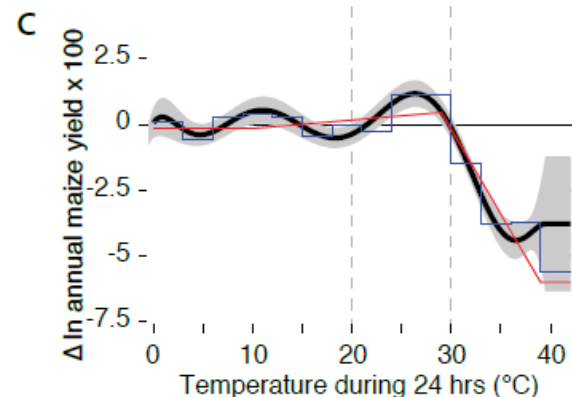

Labor supply

Roberts 2009)

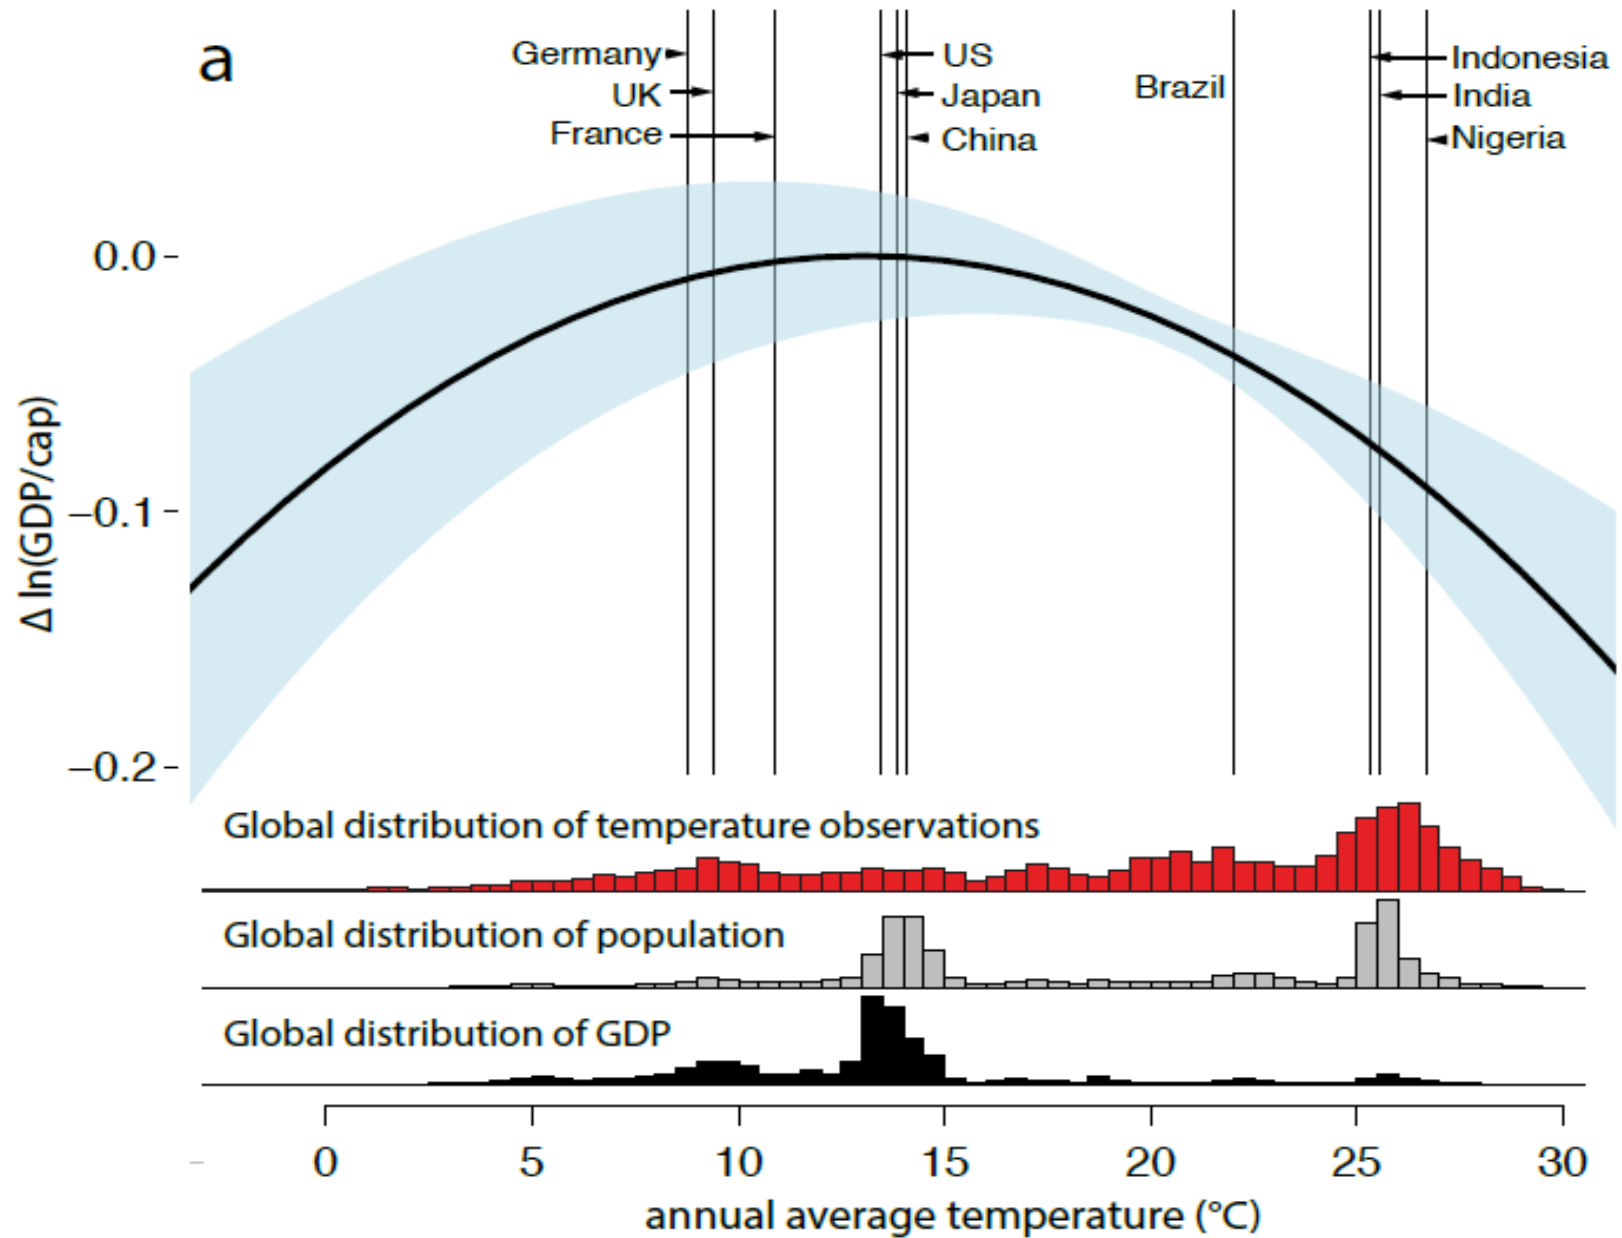

This study

- Estimate climate impacts on economic growth, allowing for non-linearities in the relationship
- Annual data for 166 countries for 1960-2010
- WDI for growth, U Delaware for temperature/precipitation:

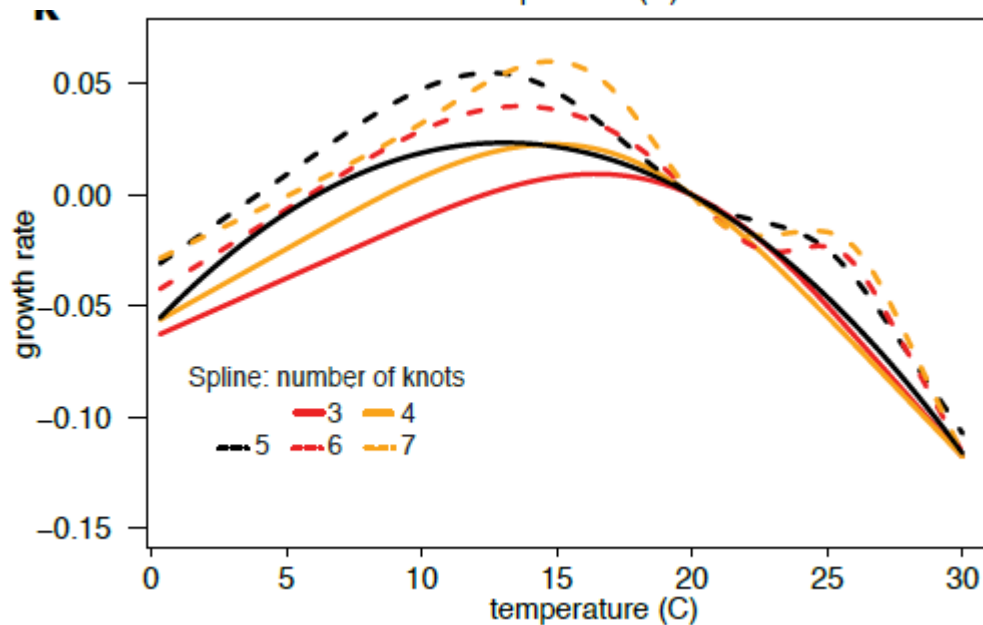

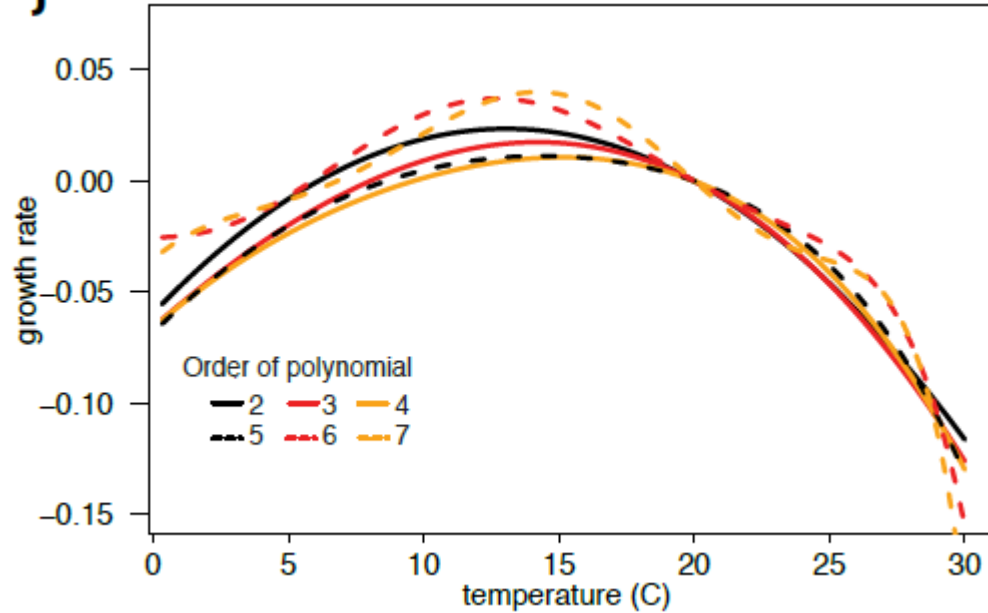

$$\Delta Y_{it} = g(T_{it}) + \lambda_1 P_{it} + \lambda_2 P_{it}^2 + \mu_i + \gamma_t + \theta_{1i}t + \theta_{2i}t^2 + \varepsilon_{it}$$

- Also include additional lags of temperature to estimate persistent growth effects
- Builds on the seminal work by Dell, Jones and Olken (2012); earlier Miguel et al. (2004), Barrios et al. (2010), and others show growth sensitive to climate.

*Quadratic temperature term, $P < 0.01$

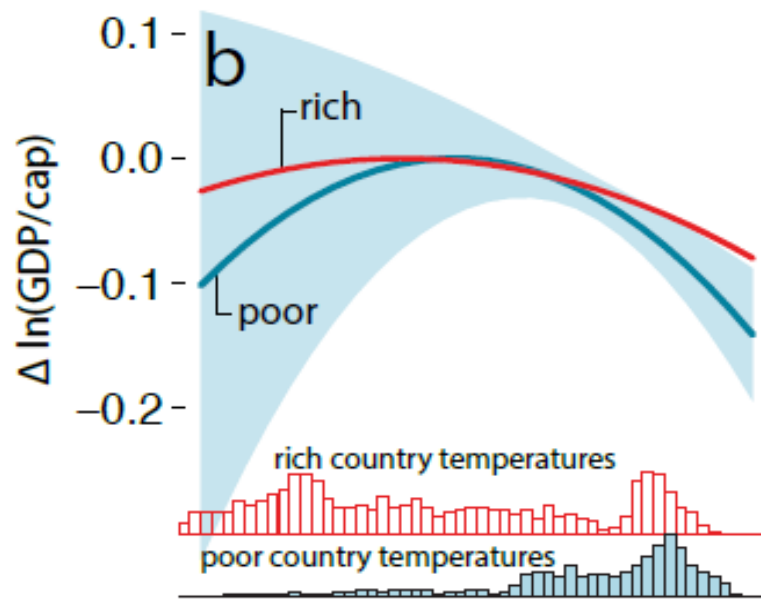

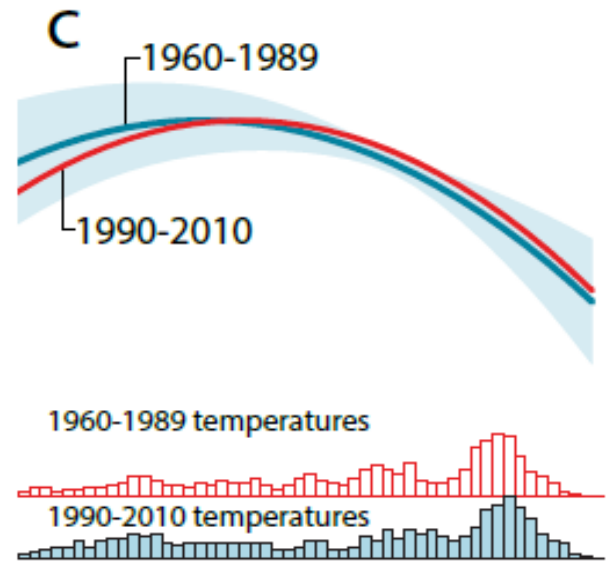

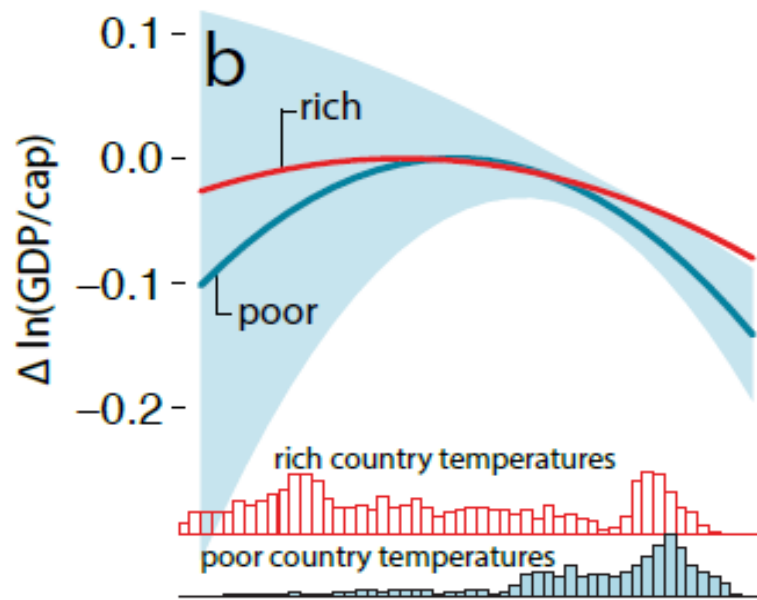

Robustness to functional form of $g(T)$

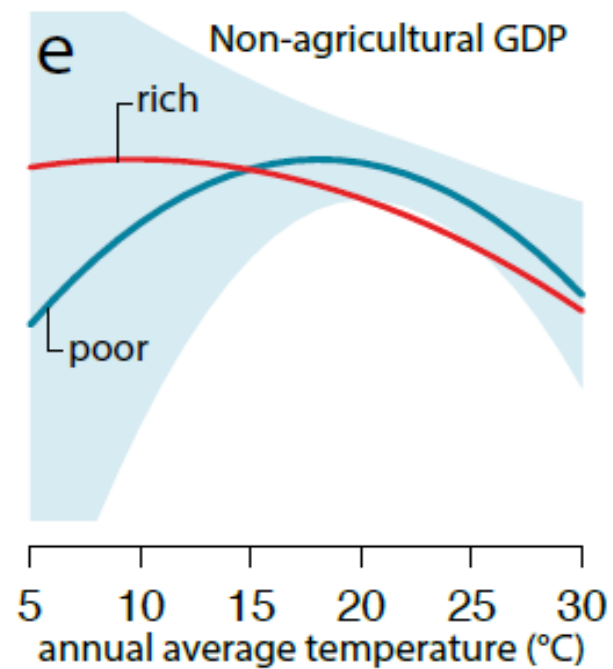

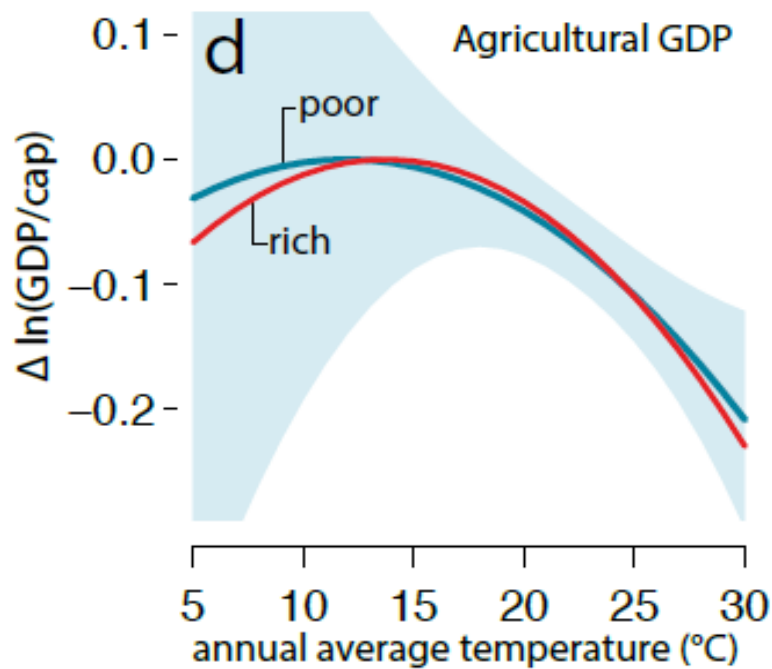

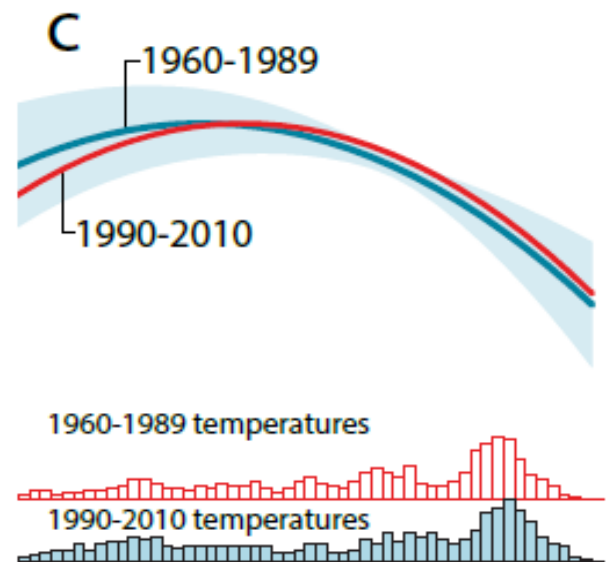

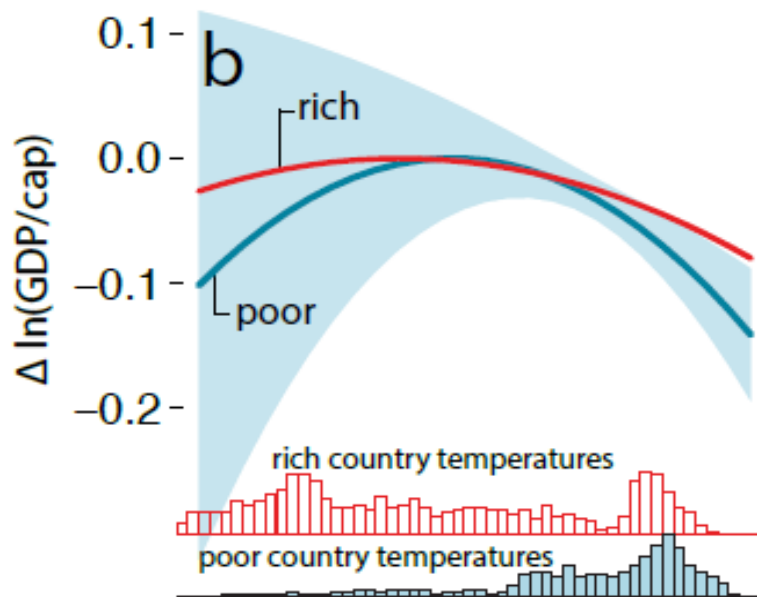

How solid is conventional wisdom?

- Conventional wisdom in economics (sometimes built in IAM's):
 - 1) Wealth insulates societies from the effects of climate
 - 2) Economic productivity has become less sensitive to climate over time (adaptation)
 - 3) Agriculture is sensitive to climate but not other sectors

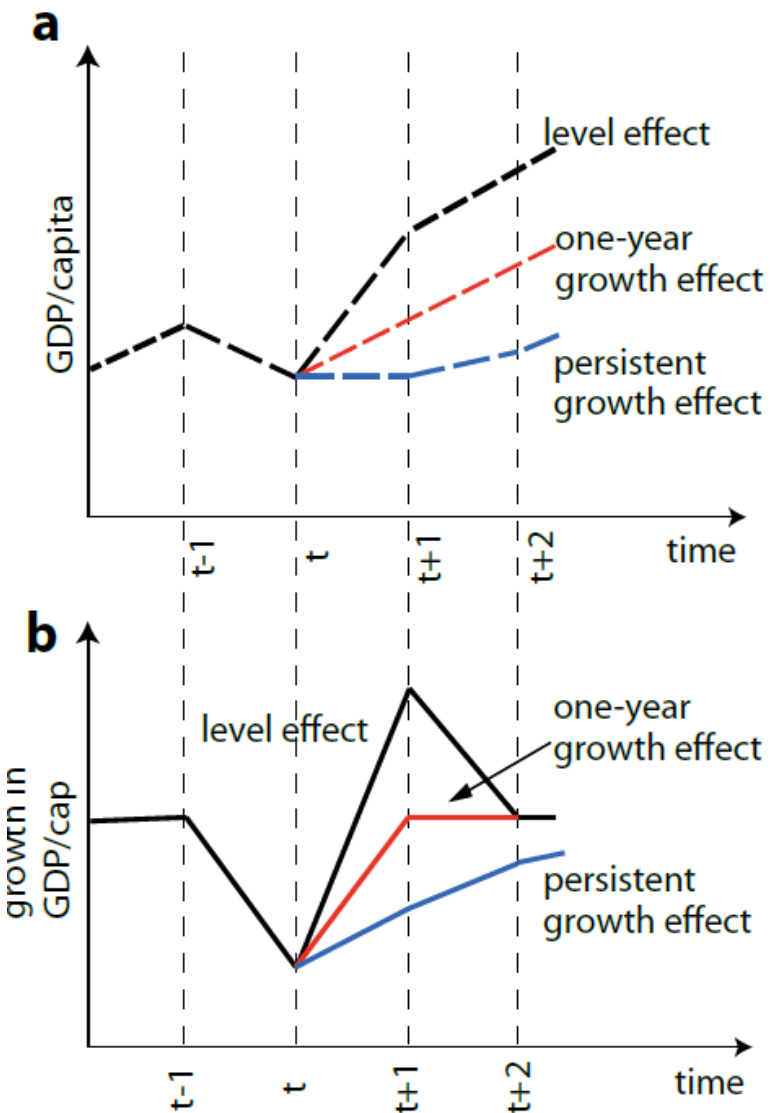

How solid is conventional wisdom?

- Conventional wisdom in economics (sometimes built in IAM's):
 - 1) Wealth insulates societies from the effects of climate
 - Perhaps partially: there is a somewhat flatter response for rich countries but not statistically distinguishable from the poor
 - 2) Economic productivity has become less sensitive to climate over time (adaptation)
 - Not for this outcome
 - 3) Agriculture is sensitive to climate but not other sectors
 - Not really: both appear sensitive to temperature, with agriculture somewhat more so (consistent with micro findings)

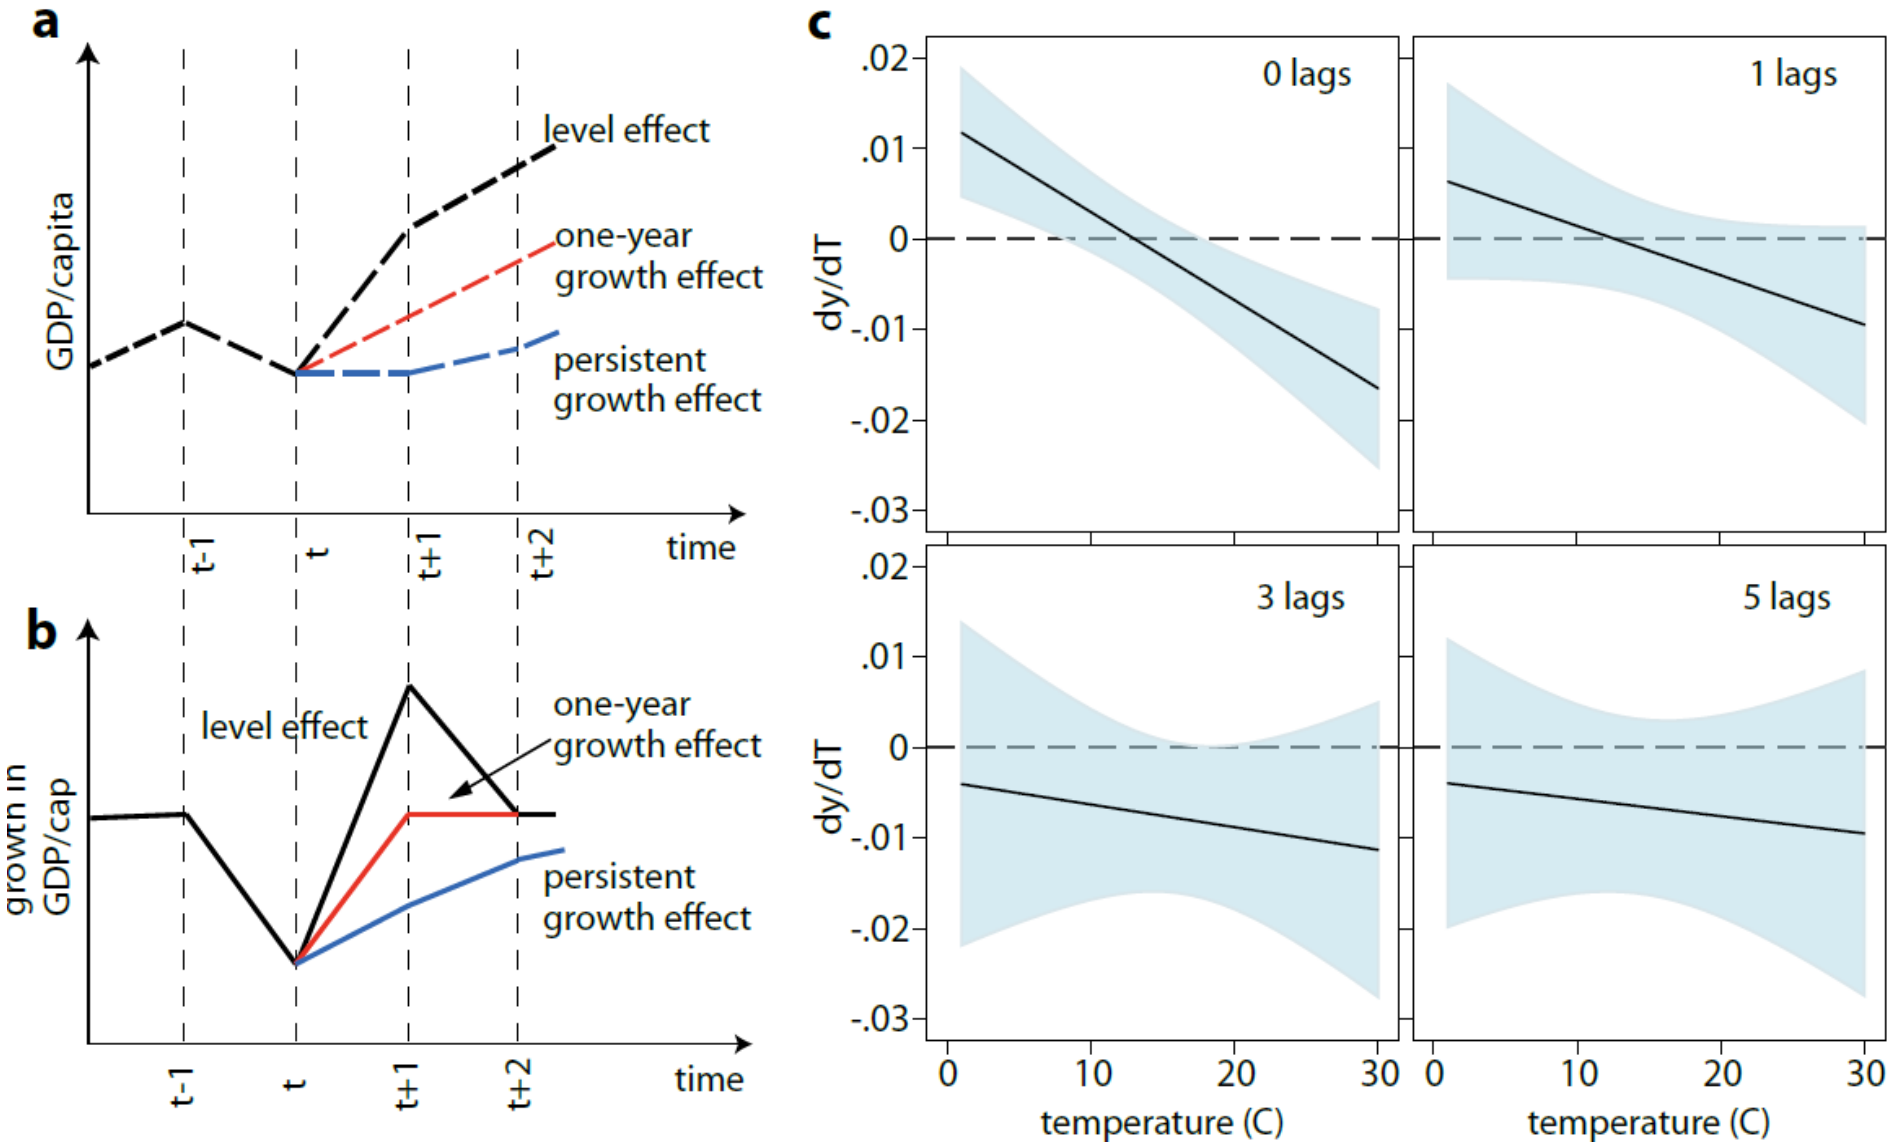

Are there persistent growth effects?

- Test for growth effects by summing up contemporaneous and lagged terms (for us, to $t-5$ years)
- “Temporary” level effects: effects in year t and $t+1$ are equal in magnitude and opposite sign

Growth effects of climate

Growth effects of climate

Are there persistent growth effects?

- Test for growth effects by summing up contemporaneous and lagged terms (for us, to $t-5$ years)
- “Temporary” level effects: effects in year t and $t+1$ are equal in magnitude and opposite sign
- There is some evidence of persistent growth effects: lagged terms sometimes statistically significant
 - Why? Shocks could reduce investment, hurting future productivity; investments may go towards adaptation measures as the climate changes (rather than productive capital); economic shocks could trigger violence and political instability that lowers productivity (Hsiang, Burke and Miguel 2013)

Projecting climate change impacts

- Project future GDP per capita for country i (Y_{it}) to 2100 as a function of the estimated temperature effects, $g(T)$:

$$Y_{it} = Y_{it-1} * \{1 + \eta_{it} + [g(T_{it}^+) - g(\bar{T})]\}$$

- Projected temperature T_{it}^+ is the median of the Coupled Model Intercomparison Project (CMIP5) ensemble, under the “business as usual” **RCP8.5 scenario** of high GHG emissions

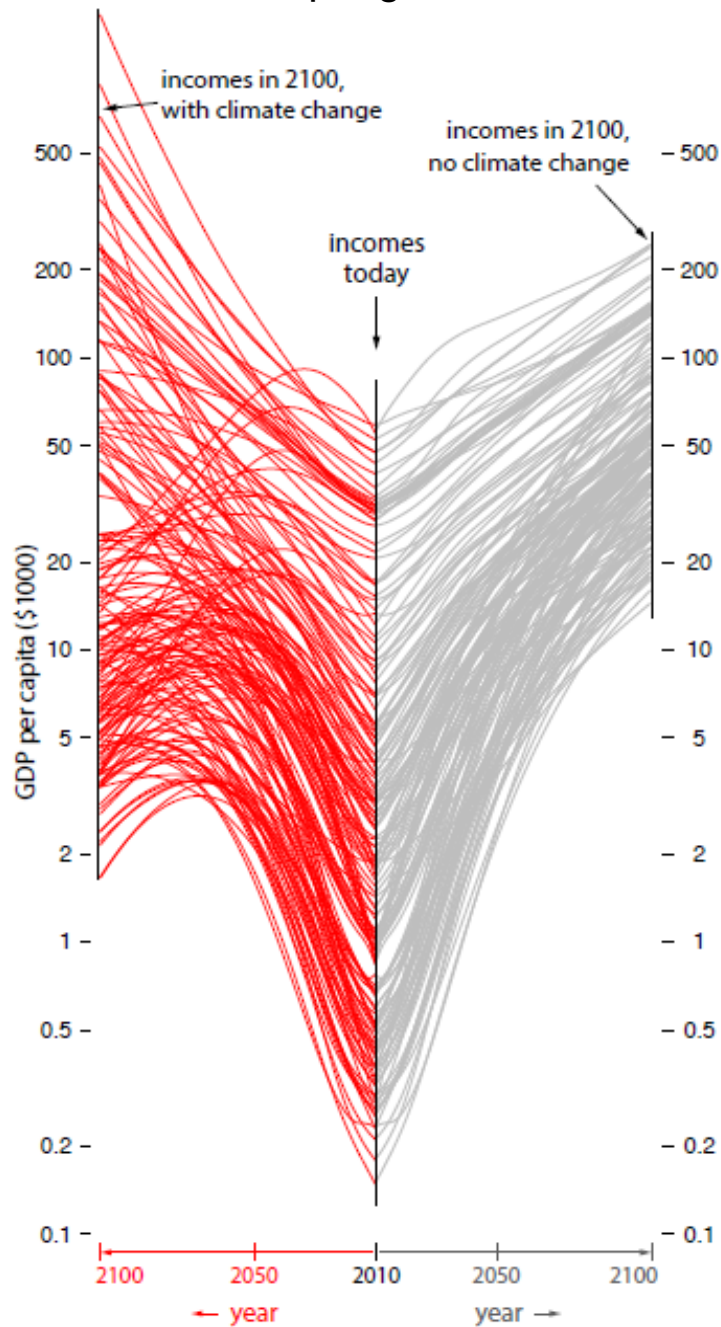

Projecting climate change impacts

- Project future GDP per capita for country i (Y_{it}) to 2100 as a function of the estimated temperature effects, $g(T)$:

$$Y_{it} = Y_{it-1} * \{1 + \eta_{it} + [g(T_{it}^+) - g(\bar{T})]\}$$

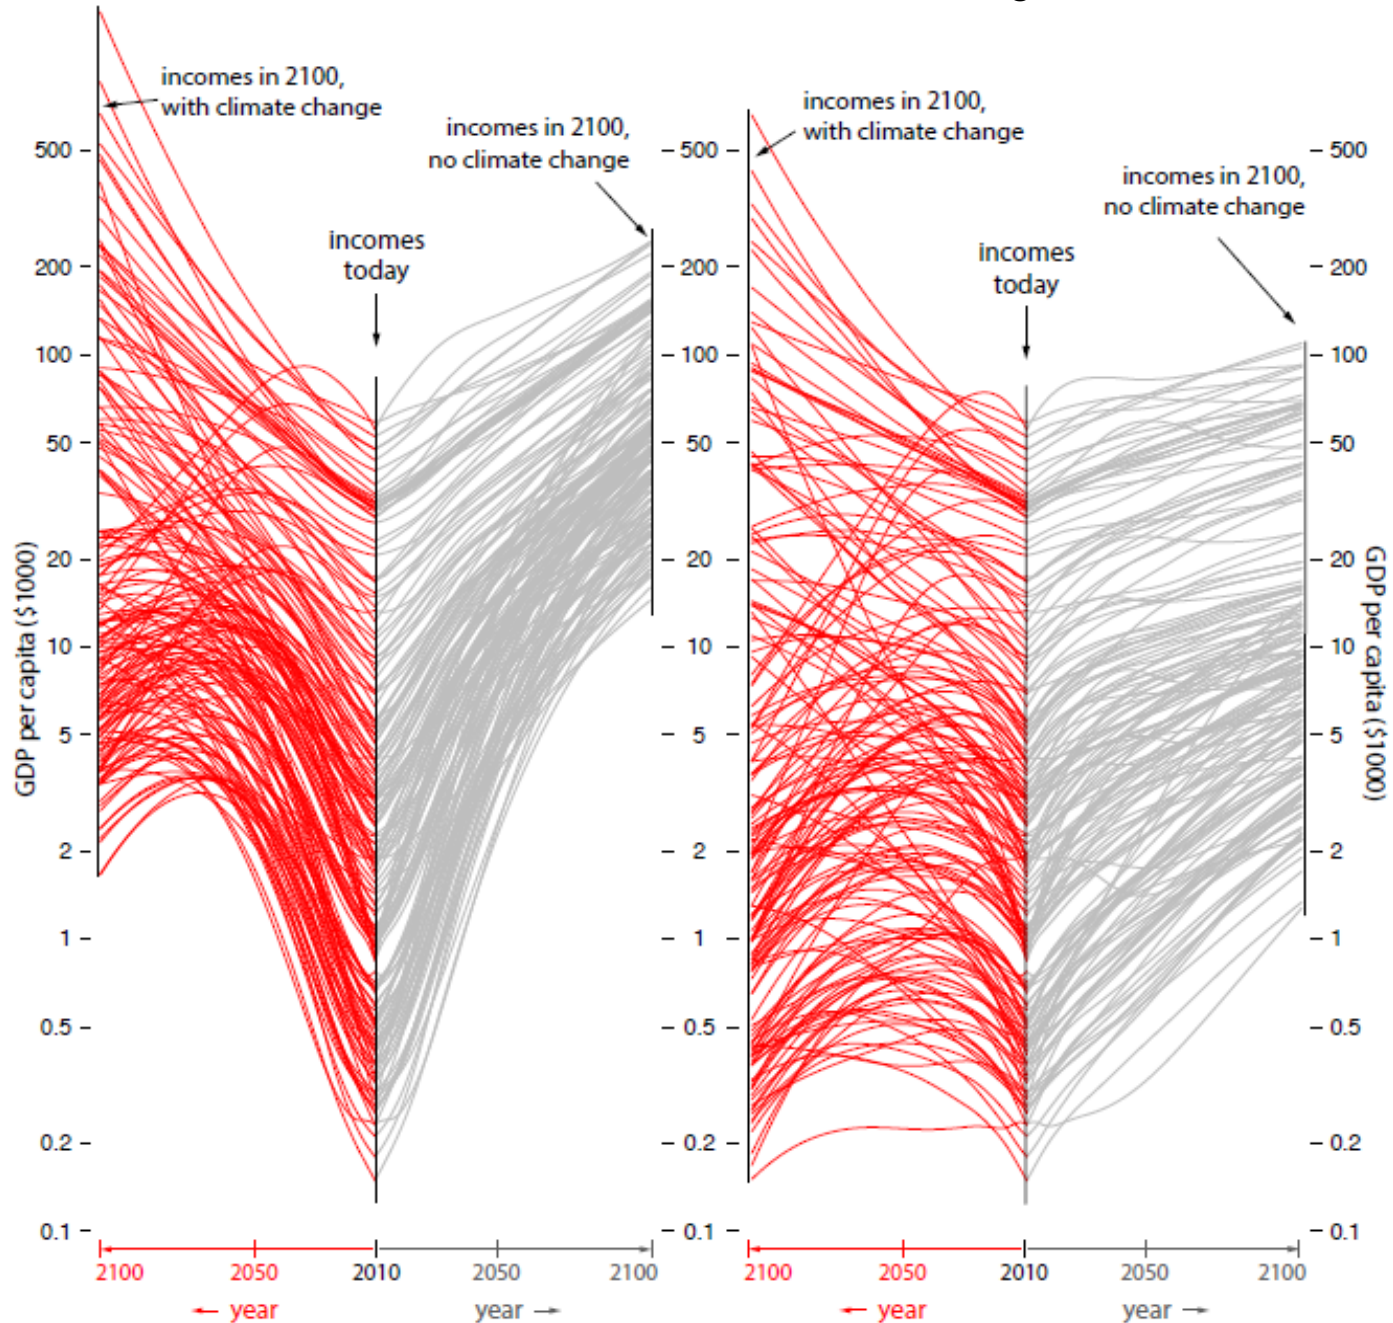

- Projected temperature T_{it}^+ is the median of the Coupled Model Intercomparison Project (CMIP5) ensemble, under the “business as usual” **RCP8.5 scenario** of high GHG emissions
- The “baseline” growth rate η_{it} is computed either as the average over 1980-2010, or using the “Shared Socioeconomic Pathways” (SSP’s) developed by the climate community
- SSP3 (slow growth, ~1% per annum); SSP5 (rapid growth, ~3%)

a (SSP5): Rapid growth scenario

a (SSP5): Rapid growth scenario

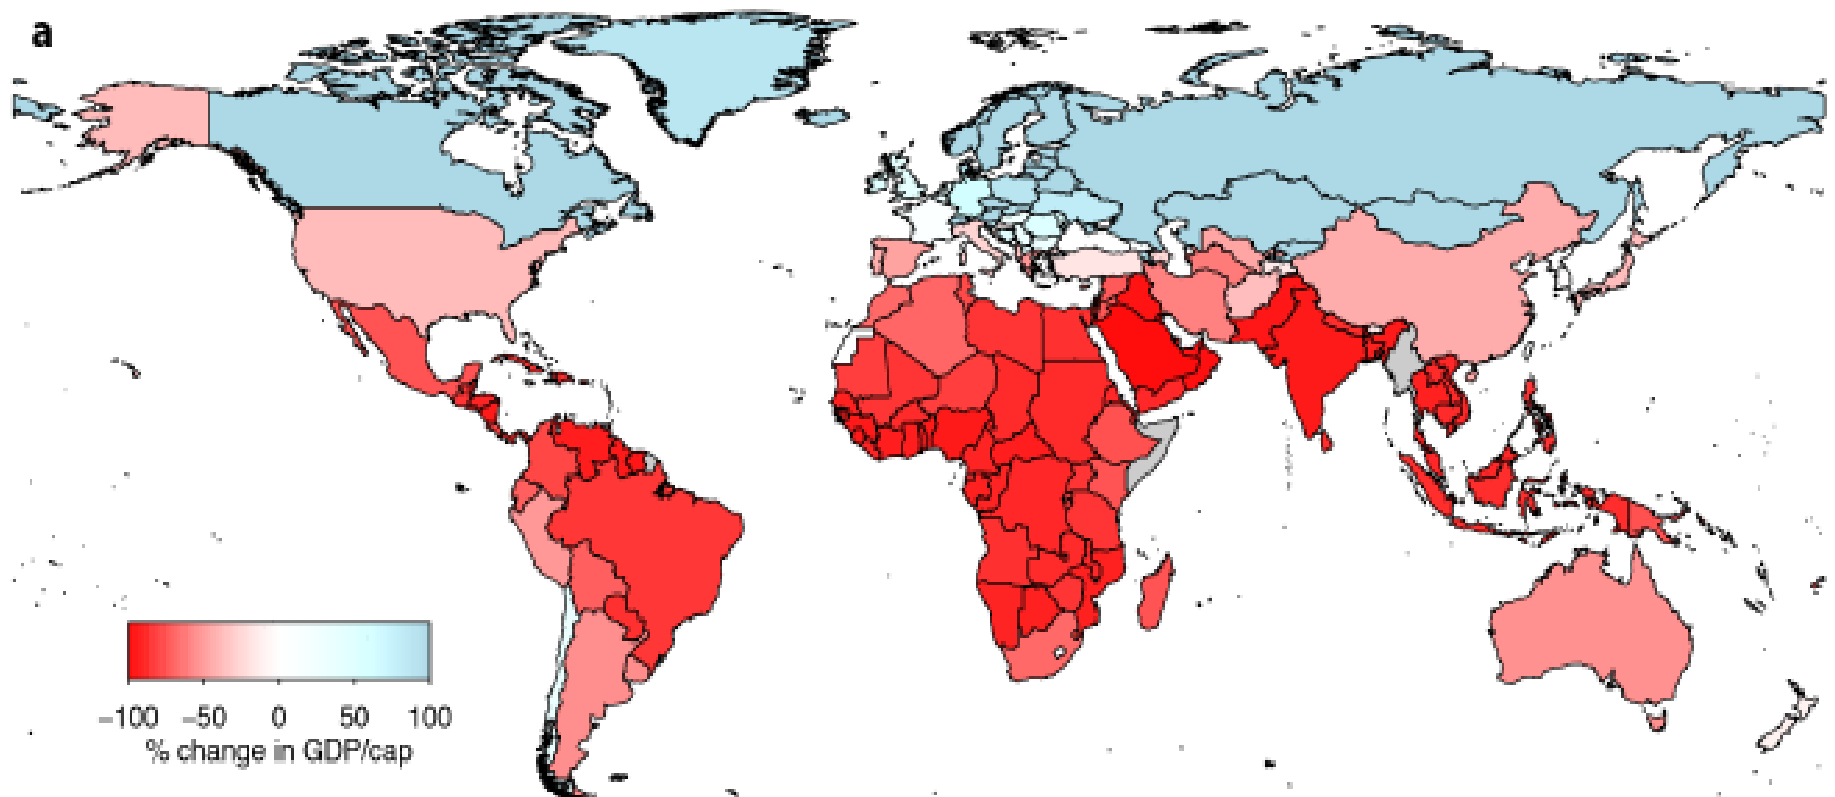

b (SSP3): Slow growth scenario

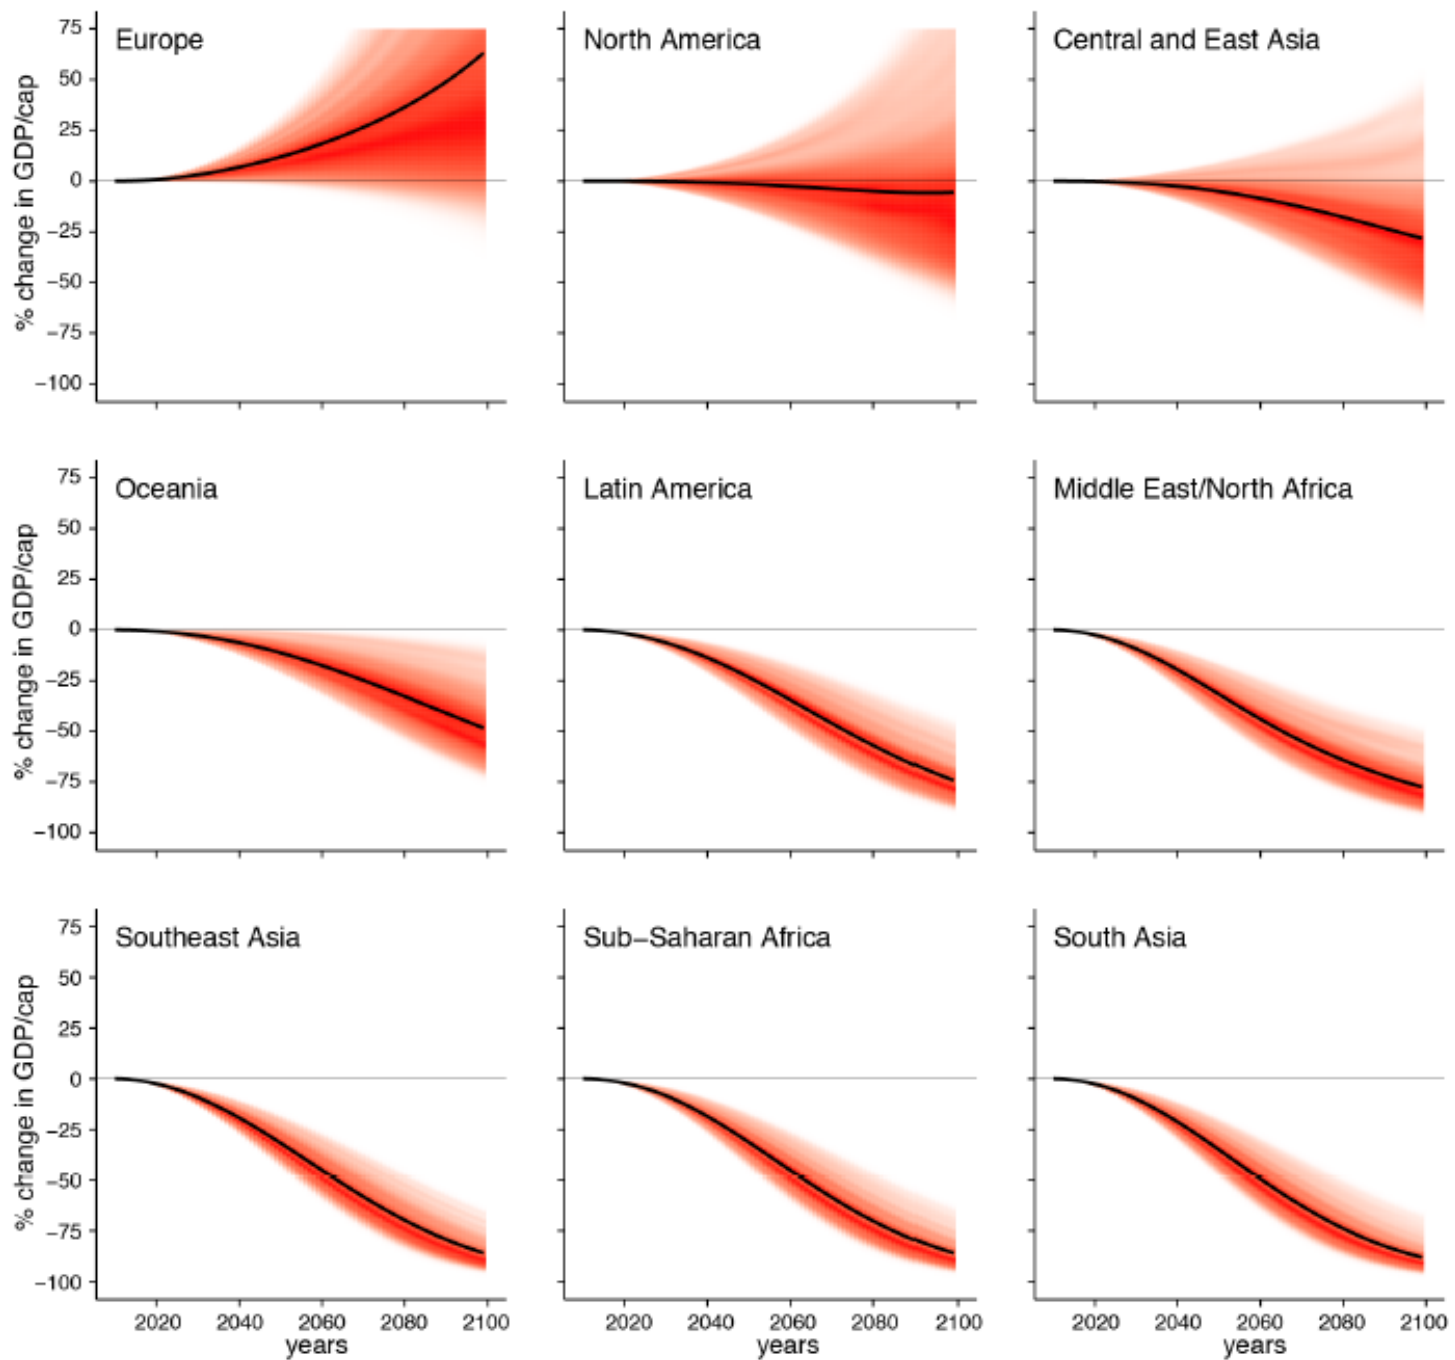

High likelihood of negative impacts

Statistic	Projected impacts under alternate scenarios of future population/income growth <i>% impact relative to world without climate change</i>		
	base	SSP3	SSP5
→ point est.	-36	-26	-23
5th	-65	-60	-58
25th	-50	-42	-39
50th	-35	-24	-21
75th	-16	2	5
95th	27	67	66
% runs < 0	85	73	71
% runs < -10	79	66	63
→ % runs < -20	71	56	51

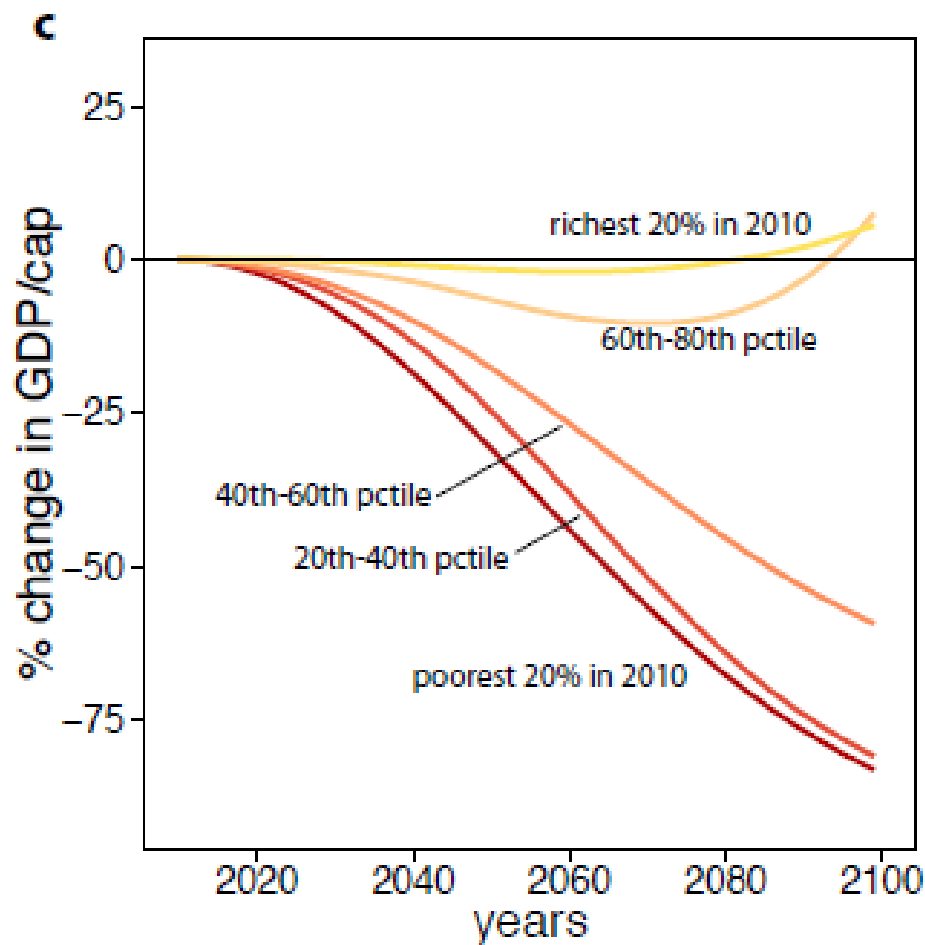

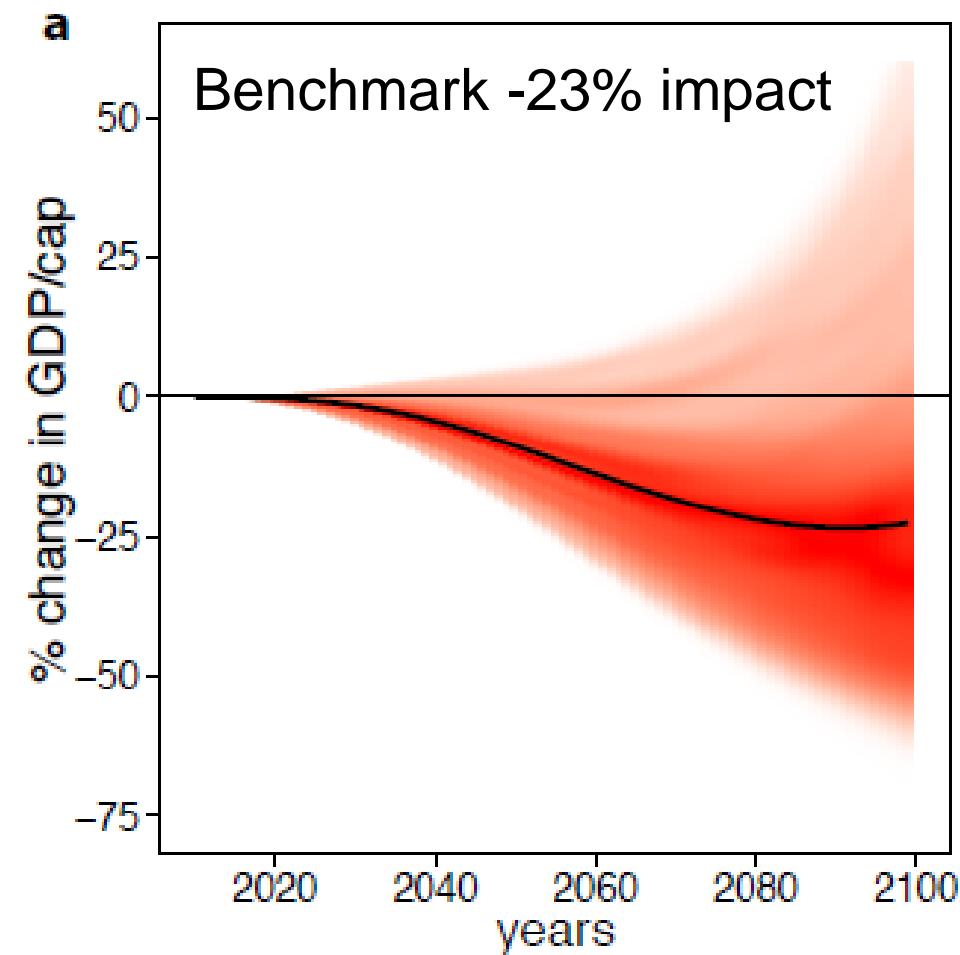

Relative to no climate change

>75% countries worse off

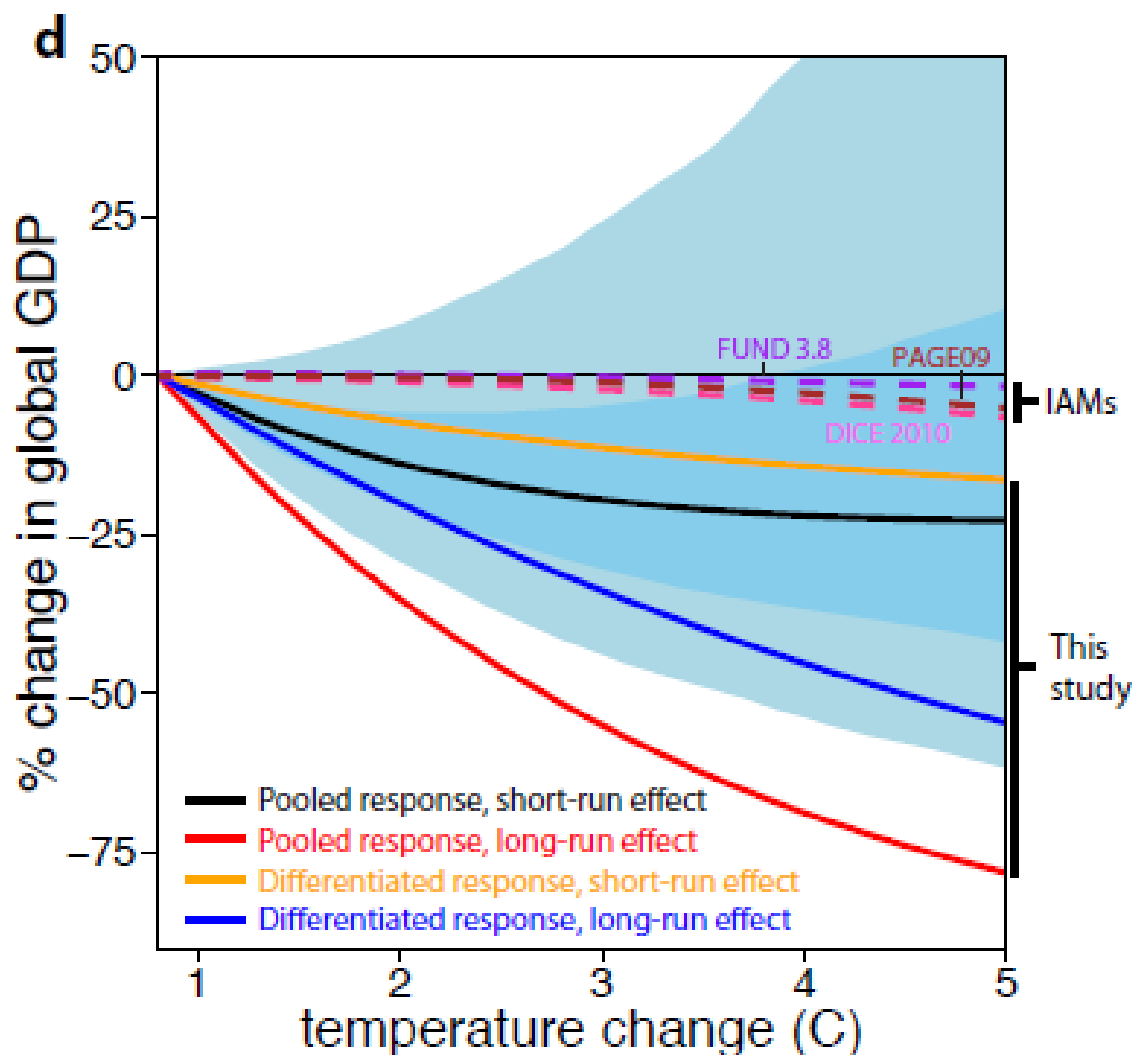

Risk of rising global income inequality

Projected effects far larger than IAM's

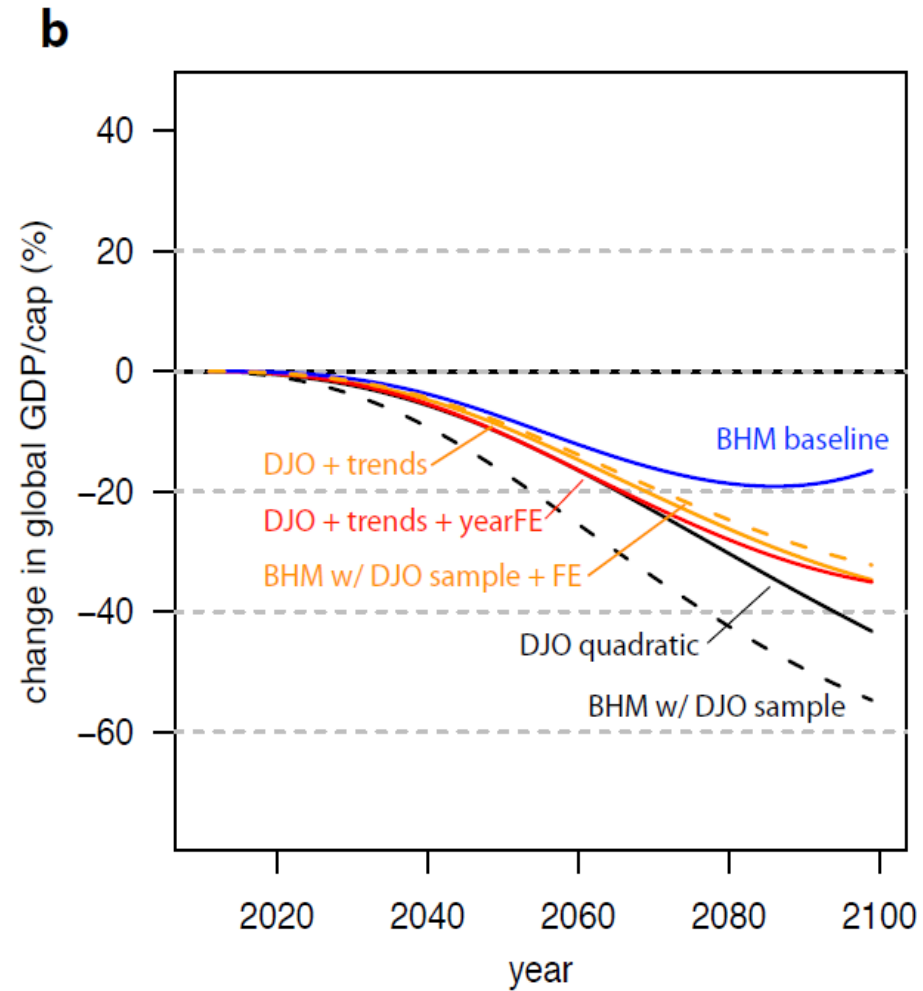

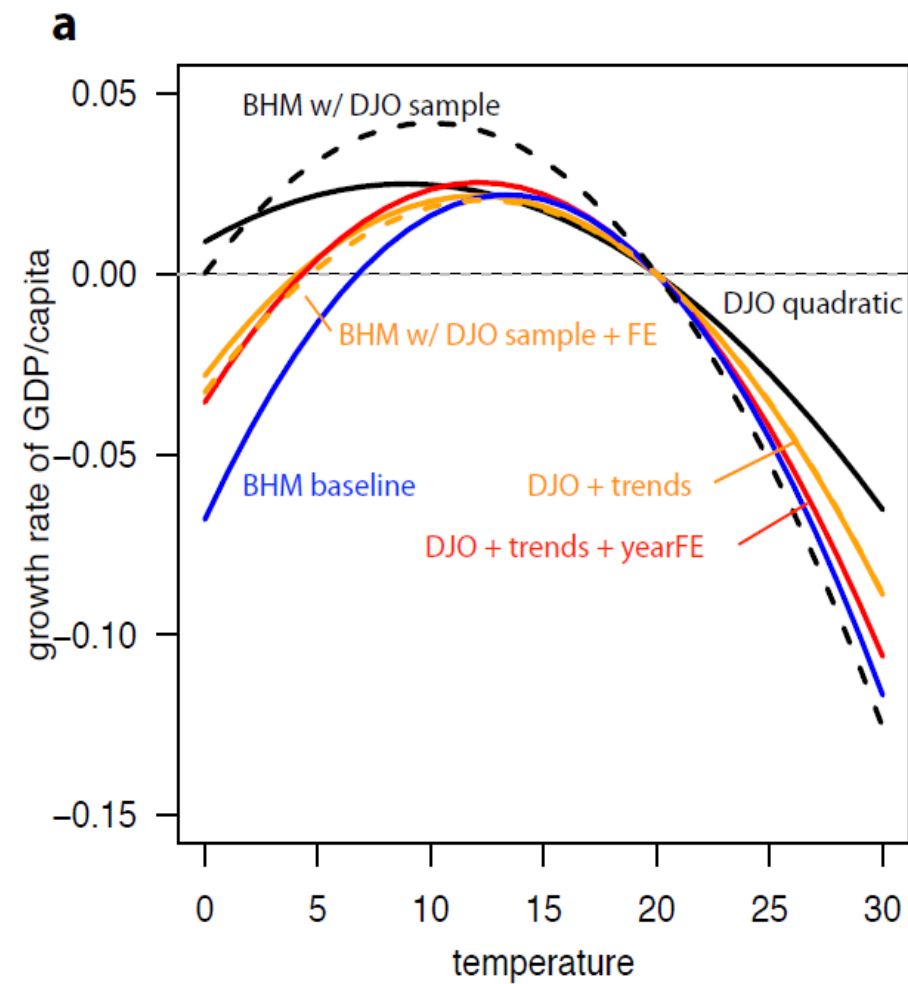

Economic growth effects are a key difference

Comparison to Dell, Jones, Olken 2012

- We use slightly longer time series, and updated data; and slightly different empirical specification than DJO 2012
 - The quadratic temperature term in DJO 2012 is only marginally significant and they focus on linear specifications, separately for rich and poor countries
- Results using a quadratic specification are very similar regardless of data series and other econometric modeling choices
- Their linear specification yields much more “optimistic” projections of future climate impacts, in part because the point estimate for rich countries is positive (but small, not significant)

Comparison to Dell, Jones, Olken 2012

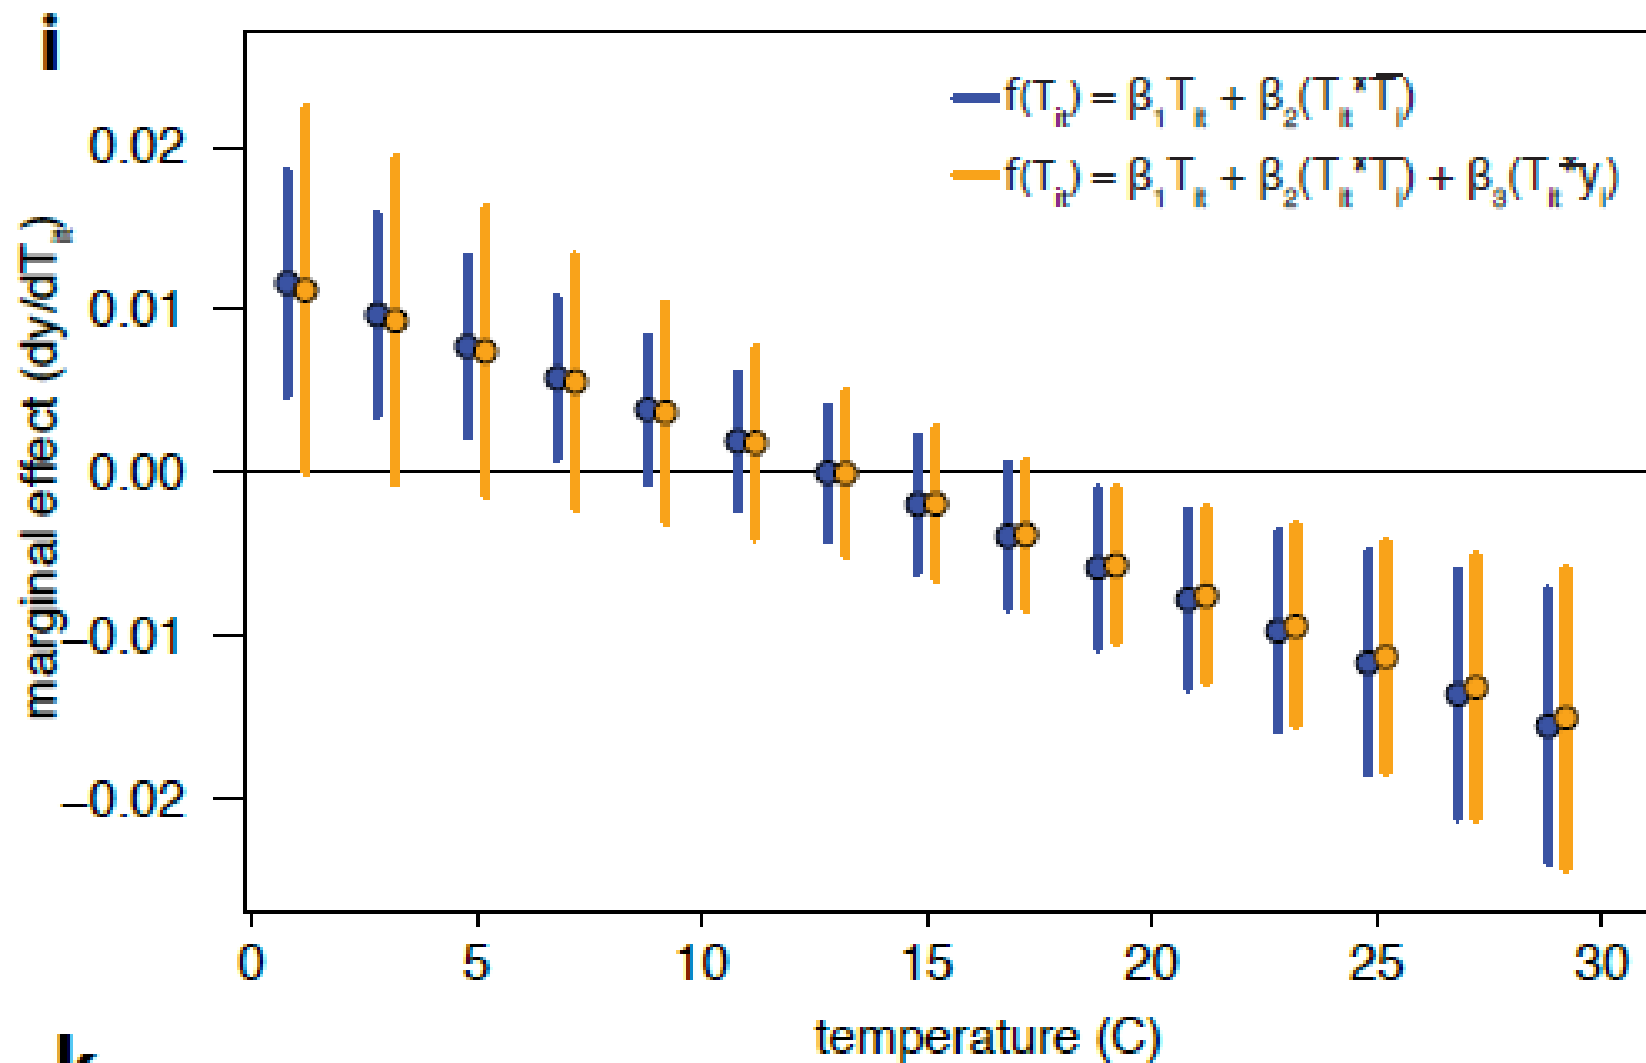

Conclusions

1. A non-linear effect of temperature on growth historically
 - No significant differences between rich and poor countries
 - No evidence of meaningful adaptation over time
2. High likelihood of large losses under future climate change
 - Under “business as usual” emissions, 51-71% odds global income per capita is >20% lower by 2100
 - Low income regions are at greatest risk
3. Loss estimates are far larger than existing damage functions, despite fact that our effects only work through temperature
 - Losses an order of magnitude larger than leading IAM’s

→ Much more investment in mitigation is likely to be optimal
